ABSTRACT

The architecture of the Western Andes is remarkably constant between southern Peru and northern Chile. An exception, however, is present near Arica at 18°S, where the Andes change their strike direction by ca. 50° and the Coastal Cordillera is absent over an along-strike width of 50 km. Although this feature has been mentioned in several previous studies, no effort has been made yet to describe and explain this peculiar morphology of the Western Central Andean forearc. Here, we propose a large-scale model to explain the Myr-long low uplift rate of the Arica Bend concerning seismic coupling and continental wedge-top basin evolution. New geomorphic and sedimentologic data are integrated with seismicity and

structural data from the literature to interpret the post-Oligocene pattern of uplift, erosion, and sediment transport to the trench. Results show that the Arica Bend has been marked by exceptionally low coastal uplift rates over post-Oligocene timescales. In addition, this uplift anomaly at the Arica Bend correlates with relatively high sediment discharge to the corresponding trench segment since late Oligocene time. We interpret that before 25 Ma, the forming seaward concavity of the subduction zone induced trench-parallel extension at the curvature apex of the overriding forearc. The subsequent low uplift rate would have then triggered a feedback mechanism, where the interplay between relatively-low interplate friction, low coastal uplift and relatively-high sediment discharge favored Myr-long relative subsidence at the Arica Bend, in contrast to Myr-long uplift of the Coastal Cordillera north and south of it.

Keywords: northern Chile, southern Peru, Coastal Cordillera, coastal uplift, seismic coupling, trench sedimentation, Andes.

(A) 1. INTRODUCTION

The western Andean margin has formed through the subduction of the Nazca oceanic plate beneath the South American continental plate since late Cretaceous (e.g Gregory-Wodzicki, 2000). The strike of this subduction zone parallels the mountain range (Fig.1). Between 17°-20°S the Andes feature a remarkable change in the strike direction by 50° from NW-SE to N-S, thereby marking a distinct deflection of the coastline. This sector of the Western Central Andes, which has been referred to as the “Arica Bend” in the literature (e.g. Wörner *et al.*, 1988; Armijo & Thiele, 1990), has been considered as one of the most conspicuous features of the mountain range. The Arica Bend presents particularities regarding (i) the arrangement of the litho-tectonic domains (Garcia & Hérail, 2005), (ii) the

absence of raised Quaternary terraces (Regard *et al.*, 2010; Melnick, 2016) and (iii) the low historical seismicity (Comte & Pardo, 1991). While the entire suite of trench-parallel domains including (from west to east): the Coastal Cordillera, the Central Depression, the Precordillera and the Western Cordillera (e.g. Charrier *et al.*, 2013) are present along most of the Peruvian and Chilean Western Central Andes for a length of >1000 km, the Coastal Cordillera gradually descends in elevation from >1000 m a.s.l. to sea-level as it approaches Arica from both sides of the bend (Fig.1). There, the along-strike profile of the Coastal Cordillera denotes a 300-km-wide and 1.4-km-deep depression with no coastal relief over a ca. 50-km-long segment between 18.2°S and 18.4°S (Fig.2).

A further particularity of the region concerns the seismicity. The entire margin between 15°-24°S has been described as a locked plate-boundary (e.g. Comte & Pardo, 1991), which means that plate convergence occurs almost exclusively during subduction earthquakes. Throughout the manuscript we will refer to the ratio between seismic slip and convergence rate with the expression “seismic coupling”, as suggested by Wang & Dixon (2004). In the Peru-Chile subduction zone, compressional stresses can accumulate for up to 200 year-long periods (interseismic) before a mega-thrust earthquake (coseismic) occurs. The seismogenic zone of the plate interface extends down to approximately 50 km in depth (Allmendinger *et al.*, 2005a; Li *et al.*, 2015) and is composed of an irregular ensemble of aseismic, conditionally stable and seismic patches (Lay *et al.*, 2012). This complex pattern of seismic coupling implies that the seismic cycle occurs unevenly both along- and across-strike. Accordingly, a remaining locked patch of margin adjacent to recently ruptured segments is referred to as “seismic gap” (e.g. Thatcher, 1989), and it corresponds to the location where the next megathrust earthquake is expected to occur.

In historical times, the Western Central Andean margin has repeatedly hosted several megathrust earthquakes such as, among many others, the 1868 M 8.8 northwest of Arica, the 1877 M 8.8 Iquique (Dorbath *et al.*, 1990; Comte & Pardo, 1991) and the recent 2001 M 8.4 southern Peru and 2014 M 8.2 Iquique slip events (e.g. Hayes *et al.*, 2014). Nevertheless, whether or not these ruptures were able to propagate through the Arica Bend has remained a matter of debate (Hayes *et al.*, 2014). It appears, in fact, that the plate interface at the Arica Bend has not experienced any historical mega-thrust earthquake (Dorbath *et al.*, 1990) and that this particular segment generally has experienced a low seismicity. Moreover, as mentioned above, the corresponding coastal area has undergone no measurable Quaternary rock uplift, in contrast to the adjacent coastal regions north and south of it (Fig.2).

Crustal deformation in response to seismic cycles can be accomplished through an elastic or viscoelastic mechanism (e.g. Savage, 1983; Li *et al.*, 2015). These end-member scenarios have been useful for studies addressing short timescales spanning several hundreds of years, when coseismic rebound equalizes interseismic deformation, whereas at the Myr-scale, re-iterated small amounts of permanent deformation need to be accommodated by long-lived brittle structures (King *et al.*, 1988). Throughout the manuscript we will use the term “long-term coupling” to refer to the fraction of convergence that is accommodated by permanent deformation within the forearc. A number of authors (Audin *et al.*, 2008; Allmendinger & González, 2010; Loveless *et al.*, 2010; Victor *et al.*, 2011; Binnie *et al.*, 2016) showed that permanent deformation in response to subduction earthquakes can be observed in the Coastal Cordillera, and that the faults accommodating this deformation have most likely been active since late Neogene-Quaternary time. In addition, Melnick (2016) showed that Myr-long uplift of the Coastal Cordillera of both southern Peru and northern Chile might be linked with the occurrence of megathrust earthquakes straddling depth levels

as deep as the Moho. Accordingly, these authors seem to suggest that the deformation of the coastal range might constitute the surface expression of processes acting at the plate interface.

In this paper, we test the hypothesis of whether the aforementioned along-strike differences in coastal uplift and seismicity could be related to characteristics of the subduction zone or the individual plates, such as: (i) the topography of the subducting plate (Hampel, 2002; Kukowski & Oncken, 2006; Contreras-Reyes & Carrizo, 2011), (ii) the obliquity of subduction (Liu *et al.*, 1995; Hampel *et al.*, 2004; Audin *et al.*, 2008), (iii) the curvature of the margin (Bonnardot *et al.*, 2008; Boutelier & Oncken, 2010), or alternatively (iv) along-strike differences in trench sedimentation and related friction at the plate interface (Lamb & Davis, 2003; von Huene & Ranero, 2003; Clift & Vannucchi, 2004; Oncken *et al.*, 2006). We will show (see discussion) that hypotheses (i), (ii) and (iii), which have already been discussed in the articles cited above, do not effectively explain the along-strike differences in long-term coupling and coastal uplift observed along the Arica Bend. We therefore investigate the validity of hypothesis (iv), concerning possible feedback mechanisms between trench sedimentation, seismic coupling and crustal deformation at a smaller time and spatial scale than has previously been done (Lamb & Davis, 2003). In particular, we will illustrate that the supply of sediment to the Pacific Ocean near Arica has been larger than in the sections to the north and south for the past tens of millions of years. This observation, contextualized in the growing subduction curvature, will allow us to develop a conceptual model that may explain the occurrence of a local decrease in seismic coupling ratio and, hence, the absence of crustal deformation and surface uplift in the coastal region of Arica during the past millions of years. This work, in summary, represents a first attempt to address this poorly understood problem and relies on the compilation and reinterpretation of existing stratigraphic and geodynamic data and new mapping and sedimentological data.

(A)

2. SETTING

(B) **2.1. Stratigraphy and landscape evolution**

The basement of the Western Central Andean forearc is an ensemble of magmatic and sedimentary rocks that were emplaced during eastward migration of the volcanic arc throughout Jurassic to Neogene time (Coira *et al.*, 1982; Wörner *et al.*, 2002; Armijo *et al.*, 2015). Since at least the late Oligocene, the uplift of the Coastal Cordillera has formed accommodation space for a late Oligocene-Miocene period of continental sedimentation (Armijo *et al.*, 2015 and references therein). In this time volcanoclastic alluvial and fluvial fans, pyroclastic mass-flows and fluvio-lacustrine sediments sourced in the uplifting Western Cordillera were deposited in the Central Depression east of the Coastal Cordillera, burying the basement with an unconformity (Tosdal *et al.*, 1984; González *et al.*, 2003; Armijo *et al.*, 2015). The surface of these deposits forms the modern pediplains, or pampas, that extend laterally over hundreds of kilometers along strike and that link the Coastal Cordillera to the Precordillera. This latter domain represents an along-strike 20-30 km-wide range mostly formed of abandoned eroded volcanic edifices.

Despite similarities in their stratigraphic architecture, the categorization of the units in the Central Depression has been different on either side of the Arica Bend. The related units have been referred to as: Azapa (25-23 Ma), Oxaya (22.7-19.4 Ma) and El Diablo (17-11 Ma) formations in northern Chile, south of Arica (Wörner *et al.*, 2002; Pinto *et al.*, 2004; von Rotz *et al.*, 2005; Wotzlaw *et al.*, 2011; Jordan *et al.*, 2014) and Moquegua C (34-25 Ma), Huaylillas (25.5-16.4 Ma) and Moquegua D (17-11 or possibly 8 Ma) formations in southern Peru, north of Arica (Roperch *et al.*, 2006; Decou *et al.*, 2011; Decou *et al.*, 2013). The continental suite is generally 1100 m thick on both sides of the bend. It reaches a maximum thickness of ca. 1800 m below the Pampa del Tamarugal in northern Chile (Fig.1) (Hartley *et al.*, 2000; Nester & Jordan, 2012), from where it thins to a few hundreds of meters

at most at the latitude of the Arica Bend (Uhlig, 1999). West of the Coastal Cordillera of southern Peru, between 16.25°-17.15°S, an up to 500 m-thick late Oligocene to early Pliocene sedimentary suite has been referred to as the Camana formation (Alván & von Eynatten, 2014) (Fig.3a). These deltaic and marine sediments, sourced mostly in the Coastal Cordillera, constitute the time-equivalent unit of the Moquegua C, Huaylillas and Moquegua D formations that are located in the Central Depression at the same latitude. South of 17.15°S, the only documented deposits west of the Coastal Cordillera are the so-called “rasas” (uplifted Quaternary marine terraces) (Fig.3c) (Ortlieb, 1996; Regard *et al.*, 2010). At the Arica Bend (18.3°S), Kober *et al.* (2006) postulated that the system feeding the 17-11 (Jordan *et al.*, 2014) to possibly 8 Ma-old El Diablo conglomerates (Von Rotz *et al.*, 2005) has been open to the ocean throughout the depositional time of this unit (Fig.3b). This situation thus contrasts with the locations north and south of the Arica Bend, where most of the clastic suite was retained by the Coastal Cordillera (Fig.3) (Roperch *et al.*, 2006; Jordan *et al.*, 2014), as documented onlap relationships show (Schlunegger *et al.*, 2010; Nester & Jordan, 2012). The uplift of the Coastal Cordillera commenced at ca. 25 Ma, as inferred from the stratigraphy of its eastern flank (Wörner *et al.*, 2002), and continued with rates in the order of 0.2 mm/y during late Neogene-Quaternary time, as the morphology of its western flank suggests (Regard *et al.*, 2010; Melnick, 2016). Indeed, these authors have shown that the steep coastal scarp and perched “rasas” are the result of wave erosion on an actively uplifting coast, modulated by sea-level oscillations.

Along the entire Western Central Andean forearc, volcanoclastic sedimentation was followed by regional monoclinical warping and canyon incision, during the late Miocene uplift of the western margin of the Altiplano (Wörner *et al.*, 2002; Farías *et al.*, 2005; von Rotz *et al.*, 2005; Schildgen *et al.*, 2007; Thouret *et al.*, 2007; Charrier *et al.*, 2013; Jordan *et al.*, 2014; Armijo *et al.*, 2015). Whether the geodynamic process driving this event is related to

mantle delamination or lower crustal flow is still a matter of debate (Garzione *et al.*, 2006; Ghosh *et al.*, 2006; Sempéré *et al.*, 2006; Hartley *et al.*, 2007; Garzione *et al.*, 2007; Garzione *et al.*, 2008; Garzione *et al.*, 2014). However, it seems that this phase of monoclinial warping of the western Andean margin was rooted, and thus linked, to geodynamic processes within the domain of the Altiplano Plateau (Barnes *et al.*, 2012; Whipple and Gasparini, 2014), causing a widespread uplift across the Central Andes. This phase of uplift and monoclinial warping might also have initiated the incision of the modern >500-m-deep valleys (e.g. Lluta, Azapa, Camarones, Caplina, Locumba) due to steepening of the forearc (Wörner *et al.*, 2002; Kober *et al.*, 2006; Schlunegger *et al.*, 2010; García *et al.*, 2011). Channel incision might have also been favoured by a slightly wetter phase during the Pliocene through larger runoff of the Andean streams (Ehlers and Poulsen, 2009; Jordan *et al.*, 2014; Armijo *et al.*, 2015). It is important to note, however, that the mentioned large-scale warping of the forearc has not been directly linked with processes operating at the interface between the oceanic Nazca plate and the continental South American plate, nor with the evolution of the Coastal Cordillera, on which this work is focused.

Following monoclinial warping and canyon incision, the landscape of the Arica region was sealed by the deposition of the Lauca-Perez ignimbrite at 2.7 Ma (Wörner *et al.*, 2000; Wörner *et al.*, 2002; Garcia & Hérail, 2005), which constitutes a relevant marker horizon for setting the base-level at that time. The occurrence of this unit at the bottom of the modern Lluta Valley indicates indeed that no net incision has affected this area since the time of deposition.

(B) 2.2. Structures

The modern structures of the Western Central Andean forearc are the expression of lithospheric and crustal scale long-lived processes linked to two motion regimes: (i) the bending of the Bolivian Orocline and (ii) the subduction of the Nazca beneath the South American plate. Most of the orocline bending occurred between 40-15 Ma (Roperch *et al.*, 2006) and might still be active nowadays (Allmendinger *et al.*, 2005b), whereas subduction has been active since late Cretaceous time (e.g. Gregory-Wodzicki, 2000).

The result of Myr-long subduction and orocline bending is the formation of a seaward-concave margin, where plates converge perpendicularly at the hinge of the concavity and obliquely north and south of it (Fig.1). Sinistral strike-slip faulting, as is the case for the Incapuquio Fault System in the Precordillera north of 18°S (Jacay *et al.*, 2002; David, 2007), accommodated counterclockwise rotation of the northern limb. Clockwise rotation was instead accommodated by dextral strike-slip faulting, as has been the case for the Atacama Fault System in the Coastal Cordillera south of 22°S (e.g. Brown *et al.*, 1983; Allmendinger & González, 2010). The segment of the forearc between ca. 18°-22°S has been ascribed to the structural inner arc of the Bolivian Orocline (Gephart, 1984; Roperch *et al.*, 2006; Allmendinger & González, 2010) and is generally characterized by dip-slip structures. Here it is important to note that the apex of the coastline bend, where Arica is located, is ~150 km offset north of the apex of the margin and of the orocline concavity (Fig.1). The forearc structures between 18°-22°S have been shown to accommodate both N-S and E-W shortening: the Atajaña and Pisagua faults in the Coastal Cordillera (Allmendinger & González, 2010) record Neogene-Quaternary N-S compression due to orocline bending. The Oxaya Anticline (Wörner *et al.*, 2002; Zeilinger *et al.*, 2005), together with the Ausipar and Copaquilla-Tignamar thrust systems (David, 2007) and other compressive flexures (Victor *et*

al., 2004; Garcia *et al.*, 2011) document E-W compression in the northern Chilean Precordillera due to plate convergence.

The Central Andes underwent a total shortening of 250-300 km (Oncken *et al.*, 2006), which was accommodated mostly by fold and thrust deformation on the eastern flank of the orogen (Mcquarrie *et al.*, 2002). In contrast, the Western Central Andean forearc accommodated no more than 3 km of total shortening since Oligocene time (Victor *et al.*, 2004) and little or no shortening after ~10 Ma (Hartley *et al.*, 2000; Schildgen *et al.*, 2007; Thouret *et al.*, 2007). Consistent with such a small amount of shortening, the margin-parallel compressive structures in the subaerial forearc are restricted to the Precordillera and limited in both extent and throw. Nevertheless, Armijo *et al.* (2015) collectively described these features as the West Andean Thrust and considered it as a relatively continuous feature along the entire Peru-Chile forearc.

A number of authors have described the kinematics of portions of the Coastal Cordillera, such as (i) the Chololo Fault System near Ilo in southern Peru (Audin *et al.*, 2008), (ii) the Atajana and Pisagua faults between Camarones river and the city of Iquique (Allmendinger & González, 2010) and (iii) Salar del Carmen fault at 23°S (Loveless *et al.*, 2010). In these localities, faults have accommodated permanent deformation within the Coastal Cordillera throughout multiple seismic cycles, and various mechanisms such as (i) earthquake slip segmentation (Audin *et al.*, 2008), (ii) uplift segmentation (Ortlieb, 1996; Roperch *et al.*, 2006), (iii) lower plate thickening and (iv) upper plate extension in response to underplating (Hartley *et al.*, 2000) have been proposed to explain their kinematics.

(A) 3. METHODS

3.1. Compilation

We compiled published data that have been collected in the framework of various disciplines encompassing structural geology, stratigraphy, geodynamics, geomorphology, sedimentology and seismicity. In addition, we integrated data from the literature with new interpretations based on field observations, mapping on Landsat satellite imagery and geomorphic analysis performed on ASTER GDEM Digital Elevation Models. A result of this compilation is shown in Figure 4, where previously documented structures are displayed together with other yet undescribed and/or unmapped faults. This map builds the basis for the grouping of tectonic features from the same area and for linking them to the well-explored fault systems, in order to characterize the motion regimes of the different areas within the forearc. Figure 4 will also serve to visualize the spatial distribution of the various forearc structures and to compare them with the regional seismicity pattern.

(B) 3.2. Post-Miocene along-strike sediment supply pattern

The forearc landscape between the Western Cordillera and the Pacific coast comprises mainly two landscape domains including: (i) the pediments (or pampas) that formed through the accumulation of sediment from laterally coalescent fans between the late Oligocene and the Miocene (Tosdal *et al.*, 1984) and (ii) the deep canyons that have been carved since the late Miocene and host the modern perennial streams (e.g. Schildgen *et al.*, 2007; Thouret *et al.*, 2007; García *et al.*, 2011). The excellent preservation of the Miocene pediplains (Székely *et al.*, 2014) allowed us to estimate the pattern of average sediment discharge to the ocean for the past ca. 10 Myr through budgeting (e.g. Kober *et al.*, 2006). We calculate these estimates by subtracting the Digital Elevation Model (DEM) of the current landscape, obtained from the ASTER GDEM, from a reconstructed paleo-surface representing the pampas (Garcia &

Hérail, 2005). This methodology infers that the pediplain has constituted a gently dipping topographic ramp prior to dissection (Kober *et al.*, 2006), which started around 10 Ma and became regionally relevant between 9 and 6 Ma (Hoke *et al.*, 2007; Schildgen *et al.*, 2007; Thouret *et al.*, 2007; Schildgen *et al.*, 2009; Jordan *et al.*, 2014). This latter surface was reconstructed within a Geographic Information System environment where each cell was assigned the maximal elevation value encountered within a 7.5-km-diameter circular window. Note that the width of the moving window was selected in order to allow the interpolation of the surface even across the broadest canyons. We then clipped the obtained volume to 4 macro-catchments, referred here to the Tambo, Ilo, Arica Bend, and Tana sectors (Table 1). Each macro-catchment represents a cluster of all the catchments that have supplied their sediments to the same along-strike segment, according to the configuration of the submarine valleys (Fig.1). We infer that all material that would backfill the current canyons of the forearc has been supplied to the ocean throughout the past ca. 10 Myr, and that this supply of sediment occurred at the same time north of the bend, at the Arica Bend itself and south of it. We additionally acknowledge that the interpolation method might yield an overestimation of the eroded volumes. However, because the uncertainties do not vary along-strike, the interpretation, which mainly relies on the relative pattern of inferred sediment flux, will not substantially be biased by this approach. In order to estimate a relative uncertainty on these values, we also re-iterated the surface interpolation and changed the radius of the sampling window accordingly (Table 1). We then calculated the standard deviation of all estimates in order to assess the sensitivity of the resulting pattern with respect to the sampling window size.

4. RESULTS

(A) 4.1. Structures

We compiled published and new structural data into a large-scale structural map (Fig.4), which shows the spatial orientation of the different deformation styles that have been affecting the Western Andean forearc between 17°-21°S. The coastal area of southern Peru presents several NE-SW oriented faults (Fig.4a). These features are up to 50 km long and restricted to the Coastal Cordillera, where they are homogeneously distributed. We relate them to the motion regime of the Chololo Fault System (Audin *et al.*, 2008) because of similar extent, orientation and spatial distribution. This structure is a composite normal-sinistral fault system that accommodated segmentation of uplift along the Coastal Cordillera since Oligocene time (Roperch *et al.*, 2006) and trench-parallel extension of the upper crust in response to segmented slip at interplate depth since at least Quaternary time (Audin *et al.*, 2008).

South of Arica, a nearly 90 km-long segment of the Coastal Cordillera has been cut by a suite of NW-SE and NE-SW trending faults (Fig.4f). Although these features show cross-cutting relationships, details regarding the relative chronologies and the slip directions cannot be precisely constrained because of multiple reactivations, causing a pattern that is difficult to decipher and has not been investigated so far.

South of the Camarones valley (Fig.4h) several N-S and E-W trending faults cut the topography of the Coastal Cordillera. The N-S trending faults show similar orientation and extent to previously documented features south of 22°S (Allmendinger & González, 2010), where they are described as normal faults that have accommodated upper plate extension. Nevertheless, cases of reversed normal faults show that these structures may change their

kinematics depending on the period of the seismic cycle (Loveless *et al.*, 2010). The E-W trending features are instead considered as reverse faults that have accommodated orocline bending (Allmendinger *et al.*, 2005a) as mentioned above.

The flat topography of the 50-km-long coastal stretch immediately north of Arica (Fig.4d) shows no surface expressions of deformation, unlike the other mentioned coastal areas north and south of it.

The topography of the Precordillera in southern Peru shows several NW-SE oriented lineaments that parallel the strike of the orogeny (Fig.4b). Among all these features, the Incapuquio Fault System (Jacay *et al.*, 2002; David, 2007) has been described as an active left-lateral lithospheric-scale structure that has accommodated anti-clockwise rotation of the southern Peruvian forearc due to orocline bending since Oligocene times (Roperch *et al.*, 2006). We therefore consider all the analogous mapped faults to follow the same large-scale kinematics.

The easternmost portion of the Central Depression inland from Arica is cut by the structures of the Oxaya Anticline (Wörner *et al.*, 2002), and by the Ausipar and Copaquilla-Tignamar thrust systems (David, 2007) (Fig.4d). These structures, which were active before ~10 Ma, accommodated a small amount of forearc shortening and steepening (Hartley *et al.*, 2000; Wörner *et al.*, 2002; Zeilinger *et al.*, 2005). In a similar structural position, but farther northwest (Fig.4c) and south (Fig.4g/i), the eastern border of the Central Depression is now uplifted to elevations higher than the Coastal Cordillera and cut by several trench-parallel blind faults. We consider these features as analogous to the compressive flexures that have accommodated small amounts of shortening throughout the Miocene (Garcia *et al.*, 2011) and that are possibly still active (Hall *et al.*, 2012), which is also consistent with the recent higher-than-average seismic activity in the area (Fig.4g/i)

At a smaller scale, between the Azapa and Tana Rivers, new mapping on orthophotos reveals that low-order NW-oriented intermittent channels are sharply deviated by 90° within a few meters, or abruptly terminate, where they have been captured by NW-SE-oriented structures (Fig.5b/d). This pattern points to a tectonic control where the drainage network of low-order channels has been preferentially oriented and reorganized along minor faults. Moreover, the propagation of debris-flow fans terminates where the slope has been locally inverted in response to compressive flexuring (Fig.5c). These commonly bivergent faults have most likely been formed through a combination of interseismic and coseismic permanent deformation, which are considered to accommodate the slip deficit (Loveless *et al.*, 2009; Allmendinger & González, 2010; Aron *et al.*, 2013).

(B) 4.2 (Post-Miocene) along-strike pattern of sediment supply

Our estimates of post-Miocene cumulative eroded volumes range roughly between 1000 and 9000 km³ (Table 1, Fig.6). The lowest value has been calculated for the Tana catchment, whose canyon is only half as deep as the Camarones valley (Fig.2a). In contrast to this picture, our estimates yield the highest value of sediment discharge at the Arica Bend, where the Coastal Cordillera is absent (Fig.6). After changing the sampling window of the surface interpolation as a sensitivity test, we found that the calculated volumes do not change significantly for diameter sizes between 5 and 10 km (Table 1). Indeed, although the standard deviation of the values can be up to 25%, depending on the chosen size of the sampling window, the ranking between the macro-catchments does not change.

Results thus show that, from late Miocene onward, the largest volumes of sediment have been delivered to the Pacific Ocean at the Arica Bend, where the Coastal Cordillera is absent and no surface expression of past and/or current crustal deformation is present.

(A) 6. INTERPRETATION

6.1. Pattern of deformation in the forearc

As shown in Figure 4, none of the deformation styles presented above seems to have perturbed the 50 km-wide flat coastal area north of Arica (Fig.4d). This observation is consistent with the occurrence of the 2.7 Ma-old Lauca-Perez Ignimbrite at the bottom of the Lluta Valley ~13 km from the coast (Wörner *et al.*, 2002; Garcia & Herail, 2005). The high erodibility of this unit suggests indeed that, if the area had experienced tectonic perturbations since the time of deposition, the ignimbrite would have been removed through channel incision in case of relevant uplift, or alternatively buried by fluvial deposits in case of significant subsidence and related sedimentation. We thus consider that this particular transect has experienced neither deformation, nor uplift of regional relevance throughout the Quaternary, possibly stretching back to the Miocene, as already hypothesized by Kober *et al.* (2006).

As also shown in Figure 4, the portion of forearc between the coast of the Arica Bend and the trench is subject to exceptionally low seismicity, which seems to imply a lack of crustal deformation in the same forearc sector. This is consistent with the documented pattern of late Quaternary uplift (Regard *et al.*, 2010; Melnick, 2016), which has involved the regions north and south of Arica, but not the coast at the bend itself.

(B) 6.2. Sediment supply to the ocean prior to forearc incision (~10 Ma)

South of the Arica Bend, stratigraphic relationships indicate that the Coastal Cordillera operated as a sedimentary barrier (Fig.3c), retaining the late Oligocene-Miocene coarse-grained clastic and volcanoclastic material (Azapa, Oxaya and El Diablo Formations of northern Chile) derived from the Western Cordillera in the Central Depression.

Volcanoclastic deposition in the Central Depression built up the pediplains that link the Precordillera with the Coastal Cordillera.

North of the Arica Bend, a large portion of the coarse-grained Oligo-Miocene material sourced in the Western Cordillera appears to have been trapped east of the Coastal Cordillera, while only a small portion mixed and/or interfingered with the deposits on its western flank. We base this interpretation on the occurrence of the coarse-grained fluvio-volcanoclastic suite comprising the upper Moquegua and Huaylillas Formations east of the Central Depression, while time equivalent deltaic and marine sediments are found in the Camana formation west of the Coastal Cordillera (Fig.3a) (Roperch *et al.*, 2006; Thouret *et al.*, 2007; Alván & von Eynatten, 2014). Provenance studies performed by Alván *et al.* (2015) indeed suggest that the Camana formation was predominantly sourced from the Coastal Cordillera itself throughout its depositional time. An exception is represented by the uppermost late Miocene-Pliocene Camana B unit, which appears to share the source with the continental Moquegua D formation, where the material was derived from the Western Cordillera.

In contrast to what we observe north and south of the bend, Kober *et al.* (2006) suggested that the coastal segment of the Arica Bend has operated as an open drainage system at least since the beginning of the Miocene. These authors related this to the absence of a sedimentary barrier (Fig.3b). We therefore infer that during the Miocene, larger volumes of sediments were supplied from the Arica Bend to the ocean compared to the adjacent coastal regions north and south of it.

(B) 6.3. Sediment supply to the ocean during forearc incision

The sediment supply data obtained through our estimates of post-10 Ma eroded volumes imply that the sediment discharge to the Pacific Ocean has been markedly different

at the Arica Bend compared to the adjacent regions. This pattern is linked to the concave shape of the forearc, which conveys six major channels (Sama, Caplina, Lluta, Azapa, Vitor and Camarones) and their loads towards the Arica Bend (Fig.1). Here, the total supplied volume is approximately twice as large as the second highest value (Tambo catchment, southern Peru) and 9 times larger than what has been inferred for the Tana catchment (northern Chile) (Table 1, Fig.6). The low value obtained for the Tana catchment is consistent with the remarkably shallower incision of its main channel (Tana river) in the Central Depression, which also seems to confirm the validity of our approach. Moreover, Kirk-Lawlor *et al.* (2013) have shown that the Tana river system has been able to breach through the Coastal Cordillera only after 3.5 Ma. Between the Tana canyon and the mouth of the Loa river (Fig.1), the Coastal Cordillera of northern Chile reaches its highest elevation, and the neighboring Central Depression has accumulated sediments also during the time when the other segments of the Western Central Andean forearc were affected by incision (Jordan *et al.*, 2014; Armijo *et al.*, 2015).

(B) 6.4. Sediment path between the coast and the trench

We have shown that sediment supply to the ocean has been higher at the Arica Bend than in the adjacent regions north and south of it. This seems to have occurred both during late Oligocene-late Miocene times and after late Miocene times respectively, as outlined above. In order to assess whether this pattern has persisted also in the submarine realm down to the trench, we need to discuss (i) possible offshore sinks other than the trench itself, and (ii) the dynamics of submarine sediment transport.

The submarine realm of the Western Central Andean wedge is characterized by a string of three forearc basins bordering the coast at depths between 400-1600 m b.s.l.. From north to south, these basins are: (i) the Arequipa Basin of southernmost Peru, (ii) the Arica

Basin at the bend and (iii) the Iquique Basin offshore northernmost Chile (González, 1989; Armijo *et al.*, 2015). Based on seismic surveys within the area, Coulbourn & Moberly (1977) and González (1989) showed that these wedge-top basins are bound by the continental scarp and by structural highs, which locally invert the west-dipping slope, thereby forming accommodation space. According to the same authors, the thickest sediment fill of the Peru-Chile submarine forearc is found in the Arica Basin, where the sedimentary pile has been estimated to reach thicknesses between 1500 to 4000 m (Coulbourn & Moberly, 1977; González, 1989). The age of these offshore deposits is unknown, but the presence of a sedimentary pile with large thicknesses seems to corroborate our findings that sediment supply to the Pacific Ocean at the Arica Bend has been larger during most of the time.

Although the along-strike continuity of these three basins is poorly constrained, 2D reconstructions provided by Coulbourn & Moberly (1977) imply that the centers of both the Arequipa and Iquique Basins are characterized by topographic lows, denoting an underfilled stage, while the deposits in the Arica Basin overlap the seaward structural high, which indicates an overfilled stage. Based on these observations, we infer that the postulated pattern of along-strike sediment supply might have not been altered by the mentioned offshore forearc basins. We emphasize, however, that because the age of these forearc basins remains unknown, we cannot constrain the chronological framework of this observation nor can we confirm the rates at which this material has been supplied.

Von Huene *et al.* (1999) observed that in northern Chile submarine sedimentation does not occur exclusively in the aforementioned basins. Accordingly, the material deposited between and beyond the basins would constitute an unstable surficial blanket that contributes to the occurrence of mass-wasting processes, such as turbidity currents and slumping. In this regard, the present bathymetry of the Arica Bend constrains the path of the submarine sediment transport processes (Fig.1). As nearly all major submarine channels between Sama

and Camarones (Fig.1) converge towards the same trench segment (offshore Arica), the large majority of the material mobilized through submarine mass-wasting processes, or supplied from the onshore streams in this region, would have eventually contributed to trench sedimentation offshore of Arica. In summary, whether the sediments have been directly deposited in the trench after overfilling the offshore basin, or supplied through mass-wasting, the trench of the Arica Bend may have received significantly larger volumes of sediment relative to the adjacent segments to the north and to the south.

(A) 7. DISCUSSION

(B) 7.1. Potential conditions affecting long-term coupling and coastal uplift

The presented stratigraphic and structural data show that subduction processes have not resulted in the uplift of the Coastal Cordillera in the Arica area since at least Miocene times, while the regions north and south of it show evidence of long-lived upper crustal deformation, resulting in the still active uplift of the Coastal Cordillera. As introduced above, we interpret this Myr-long coastal uplift pattern as the topographic expression of the degree of long-term coupling at work along the margin. In particular, the differences in uplift and seismicity (Fig.6) require a mechanism where the friction between the Nazca and South American plates is larger north and south of the Arica Bend than at the bend itself (Chlieh *et al.*, 2011; Béjar-Pizarro *et al.*, 2013; Li *et al.*, 2015). The presence of a low-friction anomaly at the Arica Bend is also consistent with the historically low seismic activity of this margin segment (Fig.4, 6), which has been related to a lower accumulation of stress in the corresponding segment of the plate-boundary (Chlieh *et al.*, 2011; Béjar-Pizarro *et al.*, 2013; Métois *et al.*, 2016). Additional support for this interpretation is offered by the concepts of critical taper wedge models (Davis *et al.*, 1983; Dahlen *et al.*, 1984). These models predict that a supercritical wedge, as inferred for the western side of the Andes by Norton &

Schlunegger (2011), is expected to deform either through stable sliding or tilting, excluding internal thickening through thrusting and/or plastic deformation. In such a state, the taper angle depends on the shear stresses at the plate interface, the dip angle of the décollement horizon and the mechanical strength of the rocks within the wedge. While the dip angle of the Nazca plate does not vary between Ilo and Iquique (Cahill & Isacks, 1992; Maksymowycz, 2015), the offshore topographic slope is $>1^\circ$ steeper in northern Chile and 0.5° steeper in southern Peru than at the Arica Bend (Fig.2; Maksymowicz, 2015) . This implies that the basal friction needed to sustain the supercritical wedge is lower at the Arica Bend than north and south of it. In the following paragraphs we examine which processes might have induced such an anomaly of interplate friction and coastal uplift.

(C) 7.1. Subducting topography

Topographic features entering the trench are considered to strongly influence the pattern of friction at the plate interface and the rate of subduction erosion (Kukowski & Oncken, 2006; Contreras-Reyes & Carrizo, 2011). At the latitude of the Arica Bend, the Nazca plate hosts the Iquique Ridge (Fig.1, 6), which is a broad region with a shallow seafloor and several seamounts. The subduction of this buoyant swell is considered to have increased the friction at the plate interface along its entire extent (Contreras-Reyes & Carrizo, 2011) and more generally, subduction of such topographic features are commonly noted to drive increased uplift at the margin (e.g. Wipf *et al.*, 2008). Therefore, while the subduction of the buoyant Iquique Ridge might explain the high seismic coupling and large subduction erosion generally observed along the northernmost Chilean margin (Kukowski & Oncken, 2006), it cannot be considered as a potential driver for the low long-term coupling that we infer at the plate interface of the Arica Bend. This would indeed require the presence of a topographic feature able to reduce the friction at the plate interface over a limited reach,

which has not been observed. Besides, a very high seismic coupling is also inferred for the segment north of the Arica Bend, offshore of Ilo (e.g. Li *et al.*, 2015), where no seamounts are being subducted. Finally, subduction of topographic features are thought to exert only a transient effect on seismic coupling (Maksymowicz, 2015), whereas we infer a Myr-long low-coupling anomaly.

(C) 7.1.2. Subduction obliquity

The angle of subduction relative to the margin's strike affects plate-convergence rates (Jordan *et al.*, 2001) and the kinematics of deformation within the forearc, as shown by Audin *et al.* (2008) and highlighted by the results of our compilation (Fig.4). The obliquity of convergence, here referred to as the angle of divergence from the margin-perpendicular, varies along the Peru-Chile trench (Fig.6). Convergence occurs orthogonally between 20.1°-20.5°S, offshore the city of Iquique, it reaches ~20° of obliquity at 22°S in northern Chile, where the Coastal Cordillera reaches altitudes higher than 1400 m a.s.l., and the maximum obliquity of ~39° occurs in southern Peru (17°-18°S), where elevations of the coastal range exceed 1000 m a.s.l.. Offshore the area of low uplift and seismicity at the Arica Bend, obliquity is ~23° (Fig.6). Consequently, the poor correlation between the patterns of subduction obliquity and inferred long-term coupling, seems to favor other possible drivers for the uplift anomaly along the Arica Bend.

(C) 7.1.3. Subduction curvature

Another driving force for the uplift anomaly near Arica might be the seaward concave curvature of the margin. In this context, results of numerical models about the evolution of concave forearc systems have shown that the curvature hinge yields a stress regime that differs from that of the neighboring limbs (Bonnardot *et al.*, 2008; Boutelier & Oncken,

2010). While Bonnardot *et al.* (2008) predicted the occurrence of extension in the hinge of a seaward concave forearc, Boutelier & Oncken (2010) postulated trench-parallel compression in the same position. The model by Bonnardot *et al.* (2008) shows that subducted material at the hinge of a concave margin tends to escape from the curvature apex towards the limbs, therefore inducing trench-parallel extension and subsidence. The authors associate the predicted extensional regime with the Oligo-Miocene extension and magmatism event observed by Jordan *et al.* (2001) in the Western Central Andean forearc. In contrast, the model by Boutelier & Oncken (2010) shows that shear traction may induce trench-parallel compression at the hinge of a concave margin. The authors relate this postulated compressional regime to the presence of a thickened crust in the curvature center (the Altiplano). Although both models provide interesting insights on the possible tectonic evolution of the Altiplano and the Bolivian Orocline, their results are difficult to relate to the Coastal Cordillera and particularly to the Arica Bend features, because our observations do not correspond with those inferred from the models. In particular, both models predict stress patterns within a scale at least one magnitude larger than observed there, both in space and time. Moreover, as already pointed out above, the symmetry of the oceanward concavity is ca. 150 km offset towards the south of the Arica Bend (Fig.1, 6), which suggests that the current stress pattern induced by the margin curvature may not be linked to today's morphology of the Arica Bend. Because we observe relative subsidence at the Arica Bend, however, we would favor the Bonnardot *et al.* (2008) model, although the structures that should accommodate the predicted extensional regime have not been observed yet at the surface, and no geophysical data is available to assess their occurrence below the sediments at the Arica Bend.

In light of these observations, we anticipate that the oceanward concavity of the margin may have exerted a significant role in initiating the tectono-geomorphic evolution of the Arica Bend, but we expect an alternative mechanism to dominate the most recent history of this feature. We justify this approach because the margin concavity of the central Andes has been migrating and changing its radius through time as a function of the shifts in convergence rate and obliquity (McQuarrie, 2002), until it eventually reached its present setting at roughly 15 Ma (Jordan *et al.*, 2001; McQuarrie, 2002; Roperch *et al.*, 2006). Therefore the subduction curvature constitutes a variable, rather than a constant in the long-term shaping of the Arica Bend.

(C) 7.1.4. Thickness of the subduction channel

Subduction channels have been described as the shear zones established between subducting and overriding plates, where they comprise a stack of polygenic sedimentary rocks with low mechanical strengths (England & Holland, 1979; Shreve & Cloos, 1986; Mancktelow, 1995). The thickness of the subduction channel strongly depends on sedimentation within the trench. Therefore, it is expected to be thin where sediment supply rates are low and thicker where the corresponding flux is larger. Moreover, this feature appears to have significant control on the frictional properties of the plate interface and the related seismic ruptures, as outlined by Ruff (1989) and Contreras-Reyes & Carrizo (2011). According to these authors, a portion of a margin characterized by a relatively thick subduction channel is likely to be less locked than adjacent segments where corresponding thicknesses are low. The subduction of unconsolidated trench sediments should increase the pore-fluid pressure, inducing in turn a decrease in interplate friction (Dahlen *et al.*, 1984). We have argued that the trench offshore the Arica Bend has received higher sediment supply than the adjacent segments north and south of it for the past ca. 10 Ma and most likely throughout

the entire Miocene. We therefore consider this long-lasting trench sedimentation pattern as a good candidate to explain the observed long-term low coupling as discussed in the next section.

We acknowledge that estimates of the current Peru-Chile trench fill published by Schweller *et al.* (1981) show a pattern of trench sedimentation that contrasts with our inferences, where sediment fill is most abundant offshore the Ocoña and Camana rivers in southern Peru (16.5-17°S), decreases towards the Arica Bend and becomes negligible in northern Chile (Fig.6). Nevertheless, the trench segment offshore the Ocoña River is also the location where the Nazca Fault Zone is in subduction (Fig.6; Contreras-Reyes & Carrizo, 2011). Accordingly, Robinson *et al.* (2006) interpreted the high seismic coupling of this segment as a direct consequence of the subduction of this highly irregular topographic feature. The same authors additionally used the rupture propagation of the 2001 M 8.4 Arequipa earthquake to confirm their initial interpretation.

Note also that data about the current trench fill cannot be used to exclude the occurrence of high trench sedimentation during the Mio-Pliocene time. In this context, it must be considered that as result of >20 Myr-long subduction processes, all sediments deposited during Mio-Pliocene times might already have been dragged into the plate interface, and that the current trench fill may represent the material that has been deposited throughout the Quaternary only. Schweller *et al.* (1981), indeed, proposed that under the current convergence rate of ~10 cm/y, the modern abundant trench fill south of 33°S in southern Chile might be younger than 1 Ma. At the Arica Bend, the minimum plate-convergence rate throughout Mio-Pliocene time has been 7 cm/y (Jordan *et al.*, 2001), which integrated over 20 Myr, yields a total of 1400 km northeastward motion of the Nazca plate

relative to the South American plate. This motion has been partly compensated by a maximum of 300 km of total Andean shortening (Oncken *et al.*, 2006) and a maximum of 60 km eastward margin retreat due to subduction erosion during the same time-span (Kukowski & Oncken, 2006). The remaining ~1000 km of Mio-Pliocene plate convergence must have been accommodated by subduction of the Nazca plate below South America. With these calculations, we emphasize that the current trench-fill data might not be appropriate to extrapolate paleo-sedimentation patterns older than Quaternary time in the Peru-Chile setting. The general lack of data about the residence time of trench sediments, however, hinders any further constraints on these inferences.

(B) 7.2. The evolution of the Arica Bend

Von Huene & Ranero (2003) have analyzed the modes of subduction erosion offshore the city of Antofagasta (~23.4°S), inferring that the frictional behavior of the sediment-starved northern Chilean margin may be analogous to that of a sediment-accreting one. Consequently they concluded that the plate interface of the Western Central Andean subduction zone may not at all be locked. However, GPS-derived measures of surface displacement in the forearc (e.g. Kendrick *et al.*, 2001) and the derived estimates of seismic coupling elaborated in independent studies (Chlieh *et al.*, 2011; Béjar-Pizarro *et al.*, 2013, Li *et al.*, 2015; Métois *et al.*, 2016), show that the seismic cycle is dominated by a stick-slip behavior, which is consistent with a locked plate interface. Accordingly, we tentatively decide not to follow the final conclusions of von Huene & Ranero (2003).

From another perspective, Lamb & Davis (2003) proposed that low sediment fluxes to the trench, as a consequence of the onset of aridity in the forearc, induced the Cenozoic uplift of the Central Andes at a large scale. Although alternative reconstructions of forearc

deformation, sedimentation and paleoclimate in the Western Central Andes have been proposed (Hartley, 2005), Lamb & Davis's idea (2003) that trench sedimentation might strongly affect seismic coupling remains valid (e.g. Contreras-Reyes & Carrizo, 2011).

Here, we propose that if trench sedimentation influences seismic coupling, then it must affect the deformation pattern of the Coastal Cordillera, which sits on the landward termination of the currently locked zone. Accordingly, we interpret the Coastal Cordillera to represent a trench-parallel upper-crustal wave front that expresses the degree to which the plate interface has been locked. This wave would then show a larger amplitude (higher mean elevation, Fig.6) where the coupling is stronger, possibly in response to sediment starvation in the trench (Fig.7a; Lamb & Davis, 2003), while the opposite would be inferred where the subduction channel has been thickened and lubricated by a larger sediment supply (i.e., the Arica Bend, Fig.7b). However, it remains unclear whether a larger sediment supply, in a relative sense, would be the cause of the low long-term coupling between the subducting and overriding plates, or the response of the low coastal uplift, which would favor the sediments reaching the ocean as discussed above. Therefore, we favor a scenario where the growing seaward concavity of the margin might have served as the initiator of what could be considered as a “chicken and egg” problem. In the following sections we propose a three-step temporal and mechanical model for the evolution of the Arica Bend.

(C) 7.2.1. Before 25 Ma: Orocline bending and differential uplift of the Coastal Cordillera

Following the model elaborated by Bonnardot *et al.* (2008), the early Oligocene formation of the Bolivian Orocline could have been accompanied by a distinct partitioning of the stresses within the forearc curvature. Accordingly, in the overriding plate, the point of maximum concavity would have been characterized by extension and subsidence, while the curvature limbs to the north and south of the bend would have experienced trench-parallel

compression and uplift (Fig.8a). In this model, the stress-pattern induced by the growing curvature would have led to the formation of a funnel-shaped forearc (which we still observe today), in which the flux of erosional products generated by the growth of the Andean orogeny would be concentrated into the subsiding Arica Bend.

(c) 7.2.2. 25-10 Ma: Volcanoclastic sedimentation pattern in a growing curvature

Once the along-strike erosional pattern had been established, a positive feedback mechanism could have initiated. The uplifting Coastal Cordillera would dam the Central Depression basin and condition the formation of endorheic drainage in northern Chile and mostly endorheic in southern Peru (Fig.3, 7a, 8b). As a consequence, low trench sedimentation would have contributed to enhance the friction at the plate interface, with the result that the compressional shortening and uplift of the Coastal Cordillera would have increased. At the same time, volcanoclastic deposition would have further contributed to the subsidence of the Central Depression through sedimentary loading (Fig. 7a). A contrasting positive feedback would have likely been established where the subsiding coast of the Arica Bend was not closing the drainage system (Fig.7b, 8b), and where long-lasting sediment discharge to the trench could have maintained the interplate friction at relatively-low levels, thereby decelerating, or inhibiting lower-crust shortening and coastal uplift.

The continental volcanoclastic stratigraphy of the Peru-Chile forearc (Fig.3) implies that these mechanisms have likely been at work from the Oligocene-Miocene boundary until ~10 Ma, although absolute estimates of the Oligo-Miocene sediment supply to the trench cannot be well constrained. Therefore, considering that the concavity of the margin kept accentuating until ~15 Ma (Jordan *et al.*, 2001; McQuarrie, 2002; Roperch *et al.*, 2006), we tentatively invoke a scenario where the evolution of the Arica Bend and the Coastal Cordillera was most likely dominated by the tectonically driven pattern of stresses in the

forearc throughout this time span. However, we do also consider that endorheic drainage south of the Arica Bend, paired with partially closed drainage north of it and an open drainage at the bend itself (Fig.8b) would have offered favorable conditions for amplifying the initiated deformational pattern.

(C) 7.2.3. After 10 Ma: Canyon incision, feedback mechanisms take over

At ca. 10 Ma the curvature of the western Andean margin was established, most of the continental sedimentation ceased and the forearc experienced a period of monoclinical warping and incision (e.g. Schildgen *et al.*, 2007). Most of this incision occurred roughly between 10 Ma and the Quaternary, when the trench offshore Arica received a larger volume of sediment than to the north and south, due to the funnel-shape of the forearc (Table 1; Fig.6, 8c). We consider it likely that this along-strike sediment discharge pattern was able to maintain, and possibly amplify, the feedback mechanisms initiated in Late Oligocene times. As already discussed above, the area that lacks surface expressions of crustal deformation (the coast of the Arica Bend) is offset from the current point of orthogonal subduction and curvature apex of the margin (e.g. Fig.1, 6). This symmetry offset suggests that in recent times (i.e. Late Neogene-Quaternary) the stress pattern induced by the margin concavity did not affect the uplift pattern of the Coastal Cordillera, which might ultimately be the expression of the positive feedback mechanisms outlined above.

Studies on modern trench-fill (Schweller *et al.*, 1981; Fig.6) show that the discussed pattern of sediment supply to the trench must have changed sometimes during the Quaternary. However, a time-lag between trench sedimentation, coastal uplift and deformation must be taken into account and still needs to be constrained.

(A) 8. CONCLUSIONS

The search for controls on the uplift anomaly in the area surrounding the Arica Bend has been a long-standing problem, which, however, has received little attention during the past years. This paper resumes current interpretations and provides a possible solution. In particular, we favor a mechanism where the formation of the seaward concavity of the Bolivian Orocline seems to have caused forearc extension at the point of maximum curvature. The resulting low uplift rate at the coastline bend would have initiated a feedback mechanism, where the interplay between high sediment supply, low long-term coupling, low seismicity and low coastal uplift has maintained a situation where the Coastal Cordillera at the Arica Bend has been absent during geological times, which contrasts to the long-lasting uplift north and south of it.

Our interpretations rely on a compilation of geological data, on estimates of sediment supply, and on mapping. Further investigations in the offshore forearc would therefore provide better constraints on the residence time of sediments in the trench and the submarine pattern of sediment transport in this poorly studied segment of the Western Central Andes.

ACKNOWLEDGMENTS

We are very grateful to Taylor Schildgen and Gerhard Wörner, whose reviews greatly helped improving the final manuscript. We do also thank Armin Dielfolder for his interest and fruitful discussions as well as Naki Akçar for his support during fieldwork. Research was financed through a grant of the Swiss National Science Foundation (project No. 200020-121680) awarded to Schlunegger. The ASTER GDEM data are a product of METI and NASA, and are distributed by the Land Processes Distributed Active Archive Center (LP DAAC), located at USGS/EROS, Sioux Falls, SD (<http://lpdaac.usgs.gov>). The Landsat and

the ANSS Comprehensive Catalog data are available thanks to the U.S. Geological Survey.

TABLE AND FIGURE CAPTIONS

Table 1 - Estimates of post-Miocene eroded volumes for three different diameters of sampling window. Left – right corresponds to North – South.

Figure 1 – Topographic map of the Western Central Andean subduction zone. The main subaerial and submarine channels are highlighted, as well as the main towns, the Coastal Cordillera and the main topographic features of the subducting plate. The range of trench marked as "orthogonal" represents the segment where the obliquity of convergence does not exceed 10°. Both submarine and subaerial topographies have been extrapolated from the 1 km-resolution GEBCO Digital Elevation Model (IOC, IHO and BODC, 2003). The along-strike pattern of post-10 Ma sediment discharge has been estimated through the subtraction of the modern topography to the interpolated late Miocene pediplain (see text for details). The macro-catchments considered for these estimates are bound by black solid lines. The rivers Ocoña, Camana, Vitor (Peru) and Loa (Chile) have been excluded because they extend too far beyond the Western Cordillera, where the paleo-topography cannot be well-constrained. The ideal tracks of the profiles shown in Fig.3 are also displayed. Convergence vector after Li *et al.* (2015). CC: Coastal Cordillera, CD: Central Depression, PC: Precordillera, WC: Western Cordillera.

Figure 2 – Swath profiles along the axis of the Coastal Cordillera (a) and across the forearc of the Western Central Andes in southern Peru (b), at the Arica Bend (c) and in northern Chile (d). The topographic expression of the uplifted Coastal Cordillera in southern Peru and northern Chile, highlighted by the occurrence of a steep coastal scarp, strongly differs from the gentle slopes of the Arica Bend. The offshore forearc slope angle α has been calculated along each margin-perpendicular swath profile. The displayed values of α represent the average of the maximum and minimum steepness of the forearc comprised within the trench and the shelf-break (black arrows). Swath band-width (a) 10 km, (b,c,d) 50 km; swath smoothing length (a) 2 km, (b,c,d) 5 km; VE vertical exaggeration; CC Coastal Cordillera; CD Central Depression; PC Precordillera; WC Western Cordillera.

Figure 3 - Qualitative cross sections of the coastal margins in southern Peru (a), at the Arica Bend (b) and in northern Chile (c). In (a) and (c) the Coastal Cordillera constitutes a sediment barrier that separates marine from continental environments. In (b) the absence of the Coastal Cordillera allows the volcanoclastic deposits to reach the marine environment. The ideal location of these profiles is shown in Figure 1. CC: Coastal Cordillera, CD: Central Depression, Cam: Camana formation, Moq: Moquegua formation, Az: Azapa formation, Ox: Oxaya formation, ED: El Diablo formation, LS: lake sediments / salar.

Figure 4 - Simplified structural map of the study area compiled from our own observations and from the literature (González *et al.*, 2003; Garcia *et al.*, 2004; Audin *et al.*, 2006; David, 2007; Audin *et al.*, 2008; Allmendinger & González, 2010; Garcia *et al.*, 2011). The seismicity contour lines represent the number of M>4 earthquakes found within an area of 15

km radius, and have been extrapolated from the ANSS Comprehensive Catalog (December 2014) and from the literature (Comte & Pardo, 1991). Most of the seismic activity currently coincides with the areas located above the locked plate boundary and with the recent volcanic arc. More details on the structures shown in this figure are available in the results section and referred to the circled letters from “a” to “i”. The top-left corner displays the location of the Gephart Symmetry Plane at the orogeny scale (Gephart, 1994).

Figure 5 – (a) Center - Satellite image of the Central Depression between rivers Azapa and Camarones. The Coastal Cordillera is highlighted in red, and the lineaments that form the northern termination of the Humayani flexure are shown with white dashed lines (Garcia et al., 2011). (b) Top left - The drainage network shows a preferred orientation along the direction of the structures. (c) Top right - Sharp change in color denotes that westward fan progradation has been interrupted by slope inversion along a minor blind fault. (d) Bottom – Local drainage reorganization along NW-SE oriented lineaments is evidenced by cross-cut relationships with the abandoned reach (black dashed line), which also seems to have been incised deeper due to localized uplift of the area comprised within the white dashed lines. Imagery source: Esri, DigitalGlobe, geoEye, Earthstar Geographics, CNES/Airbus DS, USDA, USGS, AEX, Getmapping, Aerogrid, IGN, IGP, Swisstopo, and the GIS User Community.

Figure 6 – Summary of the observed characteristics of the Peru-Chile trench between 17°-22°S. (a) Modern trench fill thickness after Schweller *et al.* (1981). (b) Post-10 Ma pattern of cumulative sediment supply to the trench according to our estimates (Table 1). The black columns are located in the middle of the latitudinal range of each macro-catchment (Fig.1). (c) Mean elevation of the coast (20 km wide swath profile). In order to compensate for the curvature of the margin, the latitude along this profile has been projected to the trench along the convergence direction. (d) Subduction obliquity, the values represent the divergence between the margin-perpendicular and the convergence vector. (e) Latitudinal range of the subducting topographic features along the trench, according to Contreras-Reyes & Carrizo (2011) and Robinson *et al.* (2006), NFZ: Nazca Fault Zone. (f) Mean earthquake density between the trench and the coast. The values represent the number of M>4 earthquakes found within a 15 km radius window.

Figure 7 - Qualitative cross sections of the Western Central Andean forearc showing the feedback mechanisms discussed in the text. (a) At e.g. 19.5°S, full seismic coupling causes relevant lower-crustal thickening and coastal uplift. The uplifting Coastal Cordillera dams the drainage, inducing continental sedimentation and sediment starvation in the trench. A positive feedback is thus triggered. (b) At 18.3°S (Arica Bend), a sediment-thickened subduction channel lowers seismic coupling, which in turn induces little or no thickening and no uplift. The resulting absence of the Coastal Cordillera keeps the drainage open, triggering positive feedback contrasting to the situation in (a). Modified from González et al. (2003) and Lamb and Davis (2003).

Figure 8 – Schematic evolution of the Arica Bend. The convergence vectors are indicated after McQuarrie (2002) and Li *et al.* (2015). (a) Before 25 Ma. The incipient margin curvature induces trench-parallel extension at its apex in the forearc and trench-parallel compression along the limbs north and south of it. (b) Between 25 and 10 Ma. The erosional and volcanic products of the growing Andes are deposited in the Central Depression, where the uplifting Coastal Cordillera acts as a barrier. Relative subsidence due to extension at the curvature apex allows the supplied sediments to reach the submarine realm and possibly initiate the feedback mechanisms shown in Figure 7. (c) Between 10 and 3 Ma. As volcanoclastic sedimentation ceases, perennial streams carve the deep canyons of the Western Central Andes. Thanks to the shape of the forearc, channel incision converges into the Arica Bend, where the eroded volume of sediments exceeds the accommodation space of the offshore basins and reaches the trench. Convergence of the submarine mass-wasting processes also contributes to focused sedimentation offshore the Arica Bend. In contrary, the curvature limbs yield lower volumes of sediments, which also do not seem to reach over the offshore basins (grey shading). This pattern of trench sedimentation favors the persistence of the feedback mechanisms (Fig.7) although the area of low coastal uplift is offset from the apex of the margin curvature.

Macro-catchment	Tambo	Ilo	Arica Bend	Tana
Coordinates of mouth	17.17°S	17.75°S	18.40°S	19.55°S
